## Abstract

The effects of exposure to different levels of ionising radiation were assessed on the genetic, epigenetic and microbiome characteristics of the “hologenome” of earthworms collected at sites within the Chernobyl exclusion zone (CEZ). The earthworms *Aporrectodea caliginosa* (Savigny, 1826) and *Octolasion lacteum* (Örley, 1881) were the two species that were most frequently found at visited sites, however, only *O. lacteum* was present at sufficient number across different exposure levels to enable comparative hologenome analysis. The identification of morphotype *O. lacteum* as a probable single clade was established using a combination of mitochondrial (cytochrome oxidase I) and nuclear genome (Amplified Fragment Length Polymorphism (AFLP) using *MspI* loci). No clear site associated differences in population genetic structure was found between populations using the AFLP marker loci. Further, no relationship between ionising radiation exposure levels and the percentage of methylated loci or pattern of distribution of DNA methylation marks was found. Microbiome structure was clearly site dependent, with gut microbiome community structure and diversity being systematically associated with calculated site-specific earthworm dose rates. There was, however, also co-correlation between earthworm dose rates and other soil properties, notably soil pH; a property known to affect soil bacterial community structure. Such co-correlation means that it is not possible to attribute microbiome changes unequivocally to radionuclide exposure. A better understanding of the relationship between radionuclide exposure soil properties and their interactions on bacterial microbiome community response is, therefore, needed to establish whether these the observed microbiome changes are attributed directly to radiation exposure, other soil properties or to an interaction between multiple variables at sites within the CEZ.

**Capsule:** Selected earthworm hologenome traits (e.g. gut microbiome) are potentially influenced by radiation exposure, but also confounding soil property variables

**Keywords:** Radioecology, <sup>137</sup>Caesium, Earthworm, DNA methylation, Microbiome,

## 56 **Introduction**

57 The Chernobyl nuclear accident on April 26<sup>th</sup> 1986 was responsible for a large-scale release of  
58 radionuclides into the surrounding ecosystem, resulting in long-term exposure of the local and  
59 wider environment. Exposure to radioactivity in controlled, high dose laboratory studies has been  
60 shown to have effects on soil invertebrate species including earthworms (Hertel-Aas et al., 2007;  
61 Rusin et al., 2019; Sowmithra et al., 2015), springtails (Nakamori et al., 2008) and nematodes  
62 (Dubois et al., 2019; Lecomte-Pradines et al., 2017). Further, research on the long-term effects of  
63 ionising radiation in the surrounds of the former power station, now known as the Chernobyl  
64 Exclusion Zone or CEZ, have provided information on the physiological and ecological responses  
65 of individuals, populations and ecosystems to chronic radiation exposure (see Beresford et al.,  
66 2016; Geras'kin et al., 2008; Hinton et al., 2007; Lourenco et al., 2016). Despite these studies,  
67 there is a lack of consensus on the long-term effects of radiation on wildlife in the CEZ, with some  
68 studies suggesting wide-scale impacts and others limited effects (Beresford et al., 2019b). Further  
69 work is, therefore, needed to understand how radiation exposure affected soil organisms,  
70 especially under long-term chronic exposure scenarios.

71

72 The soil was one of the main sinks for radionuclides released by the Chernobyl accident. The  
73 initially high levels in CEZ soils were shown to alter soil invertebrate population sizes and  
74 community structure (Krivolutsky, 1996). For example, reduced recruitment rates of the  
75 earthworms *Aporrectodea caliginosa* and *Dendrobaena octaedra* (Savigny, 1826) resulted in a  
76 population decline in contaminated forest sites (Krivolutzkii et al., 1992). Over time, however,  
77 earthworm populations at sites in the CEZ showed some recovery, such that within 3 years of the  
78 accident, immature/adult ratios and overall earthworm biomass in the previously impacted sites  
79 no longer differed from that in uncontaminated areas (Krivolutsky, 1996). Despite this rebound,  
80 species diversity has, however, remained lower at some sites (Geras'kin et al., 2008). This initial  
81 decline and recovery of earthworm populations in the CEZ in response to acute exposure may  
82 provide only a limited picture of potential response trajectory of earthworms to exposure which  
83 may also encompass chronic effects on traits relevant for long-term individual physiology and

population dynamics. For example, in a review of the impacts of the 1957 Kyshtym (Russian Urals) accident, reports indicate that soil invertebrate communities had not been restored at a contaminated site (the main contaminant being  $^{90}\text{Sr}$ ) c. 30 years after the accident (see Zaitsev et al., 2014). Given the low dispersal rates (e.g. of the order of 5-10 m a<sup>-1</sup> for earthworms which may limit recolonization potential (Marinissen and Vandenbosch, 1992), such a long-term impact of an acute radiation event would seem plausible.

The decline and potentially ongoing change for earthworm populations observed at some CEZ sites in the aftermath of the accident raises fundamental questions regarding the potentially adaptive mechanisms by which these organisms may respond to ongoing chronic exposure (as reviewed by Geras'kin et al., 2008). One possibility may lie in population recovery from a low starting density as exposure abates through radioactive decay and radionuclide transport to deeper soil layers. However, even within this scenario, the selection of tolerant individuals leading to the development of an adapted population may also play a role. At Chernobyl, both plant and fungal species have been shown to develop tolerance to radioisotope exposures (Boubriak et al., 2008; Egorova et al., 2015). However, despite evidence for the development of tolerance in earthworms to other pollutants (Fisker et al., 2013; Kille et al., 2013; Langdon et al., 2003), genetic adaptation to radionuclide exposure in this taxa has yet to be clearly established. Adaptation to adverse conditions can result both from phenotypic plastic responses, such as changes in gene expression mediated through modifications in the epigenetic gene regulation, as well as more classically through the selection of traits associated with tolerance. Additionally, changes in the structure and associated function of the host-microbiome can also play a role (Pass et al., 2015).

The concept of the “hologenome” recognises that changes in the regulation/activity of the genes of the organism itself *and* changes in the community and functional activity of mutualistic (microbial) communities can in combination contribute to the overall development of adapted phenotypes (Bordenstein and Theis, 2015). To assess how different components of the hologenome respond to radiological exposure (and other environmental co-variables), we here

measure genetic, epigenetic and gut microbiome changes occurring in earthworms (predominantly *Octolasion lacteum*) collected from multiple sites along a contamination gradient in the CEZ. Genetic trait analysis was undertaken using cytochrome oxidase 1 (COI) sequencing and the measurement of nuclear sequence polymorphisms using AFLP analysis using one restriction enzyme, epigenetic traits were assessed by DNA methylation profiling using methylation sensitive AFLP (meAFLP) conducted by comparing the first AFLP profile to those obtained using a second DNA methylation sensitive restriction enzyme. Gut microbiome structure was quantified using 16S rRNA loci sequencing. These analyses allow us to test the hypothesis that different genetic, epigenetic and microbiome traits of the hologenome show radiation exposure level dependent changes.

## **Materials and methods**

An pilot field trip to the Chernobyl Exclusion Zone (CEZ) was carried out in October 2014 to identify the earthworm species present within the zone. Twenty sites representing dominant habitats (grasslands, woodlands, wetlands) were visited. Qualitative sampling collected earthworms from a 50 m x 50 m area over a 2 h search period. This initial survey indicated that earthworms are relatively uncommon in the CEZ. Indeed, many sites lack this taxon. This limited distribution is likely due mainly to the sandy, low pH, low organic matter nature of the soils present, which are known to be unfavourable for earthworms (Edwards, 2004; Ouellet et al., 2008). Where earthworms were found, they were usually associated with the margins of water bodies, marshlands or in improved soils, such as the gardens of abandoned communities. Based on this information, a second field trip was carried out in October 2016 to collect earthworms of one or more species systematically from sites ranging in expected radionuclide exposure from background to relatively high, with wetlands identified as the main habitats for sampling.

During the second field campaign, six earthworm species, *Eiseniella tetraedra* (Savigny, 1826), *Eisenia fetida* (Savigny, 1826), *O. lacteum*, *Lumbricus rubellus* (Hoffmeister, 1843), *A. caliginosa* and *Aporrectodea rosea* (Savigny, 1826) were found at nine sampled sites. Three of these species (*E. fetida*, *L. rubellus* and *A. rosea*) were collected from a limited number of sites giving insufficient variation in radioactivity exposure for the collected specimens. Although *E. tetraedra* was collected from five sites that covered different radioactivity exposure levels, densities were very low limiting statistical power. Only, *O. lacteum* was found in sufficient, although sometimes at low, numbers across multiple sites with measured and modeled radiation exposure levels ranging from background to high. Therefore, this species has been selected for the genetic, epigenetic and microbiome trait analyses. It should, however, be noted that due to challenges in distinguishing between species based only upon morphology, additional genetic marker analysis was applied to a further earthworm species (*A. caliginosa*) in order to corroborate in field taxonomic identity. At each site, effort was made to collect multiple individuals per site within the restricted timeframe (as Governed by access permissions) that was available for collection. This was often challenging

as even at sites where earthworms were present, densities were often low. Each individual collected was treated thereafter as a separate biological replicate for that sample location.

Live earthworms were collected from the soil by digging and hand sorting. Individuals were maintained on own site soil for transfer to a local working area for identification and subsequent dissection for tissue samples. Due to the unique conditions presented by the sample site (remote location, sampling period limitations, and minimal facilities) an on-site protocol was used for sampling and tissue preservation. All earthworms were initially weighed, surface cleaned in phosphate-buffered saline to remove any adhering soil particles. The position of the worm's clitellum was used to divide the tissue into anterior (including the clitellum) and posterior section samples. To preserve sample integrity, tissues intended for later DNA extraction were cut into small pieces and placed in 1:10 ratio of sample weight to DNA/RNA shield™ lysis and preservation buffer (Zymo Research, Irvine, USA). Samples were lysed in the field using the super FastPrep™ handheld homogenizer and Lysing Matrix E (both from MP Biomedicals, Eschwege, Germany). Lysed samples and sampled soils (to 10 cm depth) were transported back to the main laboratory and stored at -20°C prior to DNA extraction. The soils sampled at each site were also used for radionuclide (Cs-137, Sr-90, Am-241, Pu-total isotope) activity measurements for dosimetry calculation. This augmented the simple measurement of air dose rate made *in-situ* at each site.

#### *Radionuclide Measurement and dosimetry approach*

Soil and earthworm <sup>137</sup>Cs concentrations were measured using gamma spectrometry (Ge and NaI scintillation detectors, Canberra). Whole earthworm and earthworm soil gut measurements of <sup>137</sup>Cs were carried out when samples were available. Soil <sup>90</sup>Sr concentrations were determined using beta spectrometry of the daughter nuclide <sup>90</sup>Y, and <sup>241</sup>Am using low energy gamma spectrometry. Pu concentrations (total Pu-isotopes: <sup>238</sup>Pu, <sup>239</sup>Pu, <sup>240</sup>Pu) were determined after sample dissolution (65% HNO<sub>3</sub>), anion exchange separation (BioRad AG 1 × 8, 100–200 mesh) and co-precipitation using <sup>242</sup>Pu added as a yield tracer. These samples were then counted using

a planar ion implanted silicon detector. All methods were calibrated against standards and counting errors were typically <3% for  $^{90}\text{Sr}$ , <7% for  $^{137}\text{Cs}$  and <20% for the Pu isotopes.

Controversies in interpreting results from field-based radioecology studies can arise due to an incomplete assessment of actual organism exposure (Bonzom et al., 2016). Thus, while external dose rates can provide an indication of exposure at sites, they usually underestimate actual doses received by an organism, since they do not include the contribution from internalised radionuclides. Therefore, we chose to estimate exposure as weight absorbed dose rate, which includes the contribution of all radiation types (alpha, beta and gamma emitters) from all exposure pathways (internal and external), as opposed to just ambient external dose rates measured with dosimeters (e.g. Moller and Mousseau, 2009; Uematsu et al., 2015). The approach to dosimetry assessment for all sites used a stepwise approach that: 1) recorded air dose rates and ranges (mGy/hr) at the soil surface and 1 m above ground at each collection sites; and 2) used the measured activity levels in soils to estimate the relative internal and external dose rate contributions of each radionuclide to earthworm exposure. Dosimetry modelling was carried out within a tier 3 assessment using the ERICA tool, a software system that has a structure based upon the tiered approach to assessing the radiological risk to terrestrial, freshwater and marine biota (Brown et al., 2008), using the creation of organisms (different earthworm sizes) and site-specific data. Measured tissue concentrations of  $^{137}\text{Cs}$  were used to calculate internal dose rates, while the ERICA default transfer ratios for earthworms were used for the other radionuclides (Popic et al., 2012). Weighting factors of 1, 3 and 10 were used for gamma and beta > 10 keV, beta < 10 keV and alpha radiation, respectively. Based on the radionuclide concentration in soil and the sampled organism, external and internal dose rates ( $\mu\text{Gy h}^{-1}$ ) were calculated and used to determine total weight absorbed dose rates.

#### *DNA extraction*

Following sample return to the main research laboratory, a protocol was developed which enabled the co-extraction of the earthworm and microbial DNA from the tissue and gut microbiome

samples. Preserved tissue lysate was extracted using the Zymo research ZR-96 soil microbe DNA kit™, with the following modifications. Prior to DNA extraction samples were thawed, then incubated with 2 µl proteinase K (Promega) for 1 hour at 20°C. All samples underwent a further mechanical lysis step on a fast prep 24 (MP Biomedicals) at 5 k for 30 sec. Lysed samples were centrifuged at 2100 g for 5 minutes and 250 µl of lysate combined with 750 µl soil binding buffer. All further steps were carried out according to manufacturer's protocol. Anterior (head) and posterior (tail) samples were extracted separately for analysis of earthworm genomic and microbiome traits, respectively. Large worms often contained more tail tissue than optimal for each lysis tube, where this was the case, the available tissue was spread across a number of tubes, from all of which DNA was extracted. To ensure that the entire microbiome was represented accurately, the results from all assessment for each individual worm were pooled.

### *Genotyping*

DNA samples extracted from the body wall from the anterior proportion of the earthworm were used for the corroboration of field species identification. Approximately 20 ng of DNA template was used to amplify ~710 bp region of the mitochondrial cytochrome oxidase subunit I (COI) gene, in a 50 µl total reaction, following the addition of; 0.4 µl of taq polymerase (Sigma), 1 µl of 10 µM dNTP mix (Bioline), 0.5 µl bovine serum albumin (New England Biolabs), and 0.5 µl of 100 µM primers LCOI1490F and HC02198R (Folmer et al., 1994). Amplification conditions were as follows: 95 °C for 2 min, then 35 cycles of 95 °C for 1min., 40 °C for 1 min, and 72 °C for 1:30 min, with a final extension at 72 °C of 10 min. PCR products were electrophoretically analysed and then purified using the ZR-96 DNA Clean-up kit™ (Zymo research). Purified PCR product was diluted at a 1:10 ratio and 1 µl used separate F and R sequencing reaction carried out using 1 µl BigDye™ terminator V 3.1 reaction mix (Applied Biosystems, USA), 1.5 µl BigDye™ terminator V 3.1 buffer, 1 µl of 3.2 µM primer solution, on an Applied Biosystems 3730 genetic analyser. Because of inconsistent amplification using LCOI1490F and HC02198R, a custom additional internal sequencing primer was designed and included for this study COI\_lumbricF\_seq (5'-TACAGCCACGCATTCGTTA-3'). Sequencing reactions were purified using Big Dye®

Xterminator™ purification kit (Applied Biosystems, USA) and sequenced using ABI PRISM® BigDye v3.1 Terminator technology (Applied Biosystems). Resultant sequences were base called, quality checked and assembled using Sequencher V. To act as suitable phylogenetic outgroups resultant contigs were aligned using ClustalW with reference COI sequences sourced from the barcode of life (BOLD) database, NCBI genebank and unpublished reference sequences from native worms sourced in UK (OS1). Optimal likelihood settings were determined to be TVM+G through the implementation of the Akaike Information Criterion in JModelTest V2.17 (Darriba et al., 2012; Posada, 2008). PAUP4b8 was used to generate a Neighbour Joining (NJ) tree using the likelihood criterion (with optimal settings), and bootstrap support values for 1000 replicates. The resultant tree (OS2) was used to determine the taxonomic affiliation of each earthworm and identities corroborated via inclusion in the nearest supported cluster. For *O. lacteum*, a set of successfully amplified product sequences clustered with *O. lacteum* COI sequences available from BOLD within the constructed phylogenetic tree, supporting the morphological identification for these individuals. For a remaining set of *O. lacteum* individuals (38 of 72 individuals), amplification of the COI gene failed, despite best efforts to optimize template, primers and reaction conditions for PCR. Hence, support for the morphospecies identification for these individuals was not achieved through COI sequencing. For these samples a combination of onsite morphological taxonomy and distinct species separation through AFLP profile (see Supplementary Fig. 1) was used to verify species identity.

#### *Microbiome characterisation*

Approximately 20-30 ng of template DNA collected from samples was amplified using Q5 High Fidelity Polymerase (New England Biolabs, Hitchin, UK), each sample reaction include a unique barcode-primer combination to allow separation of sequences associated with the different individuals (Kozich et al., 2013). Amplification conditions consisted of 25 cycles of an initial 30s, a 98°C denaturation step, followed by annealing phase of 30s at 53°C, and a final extension step lasting 90 sec at 72°C. Primer sequence was based on the universal bacterial primer sequence combination 341F and 806R, producing amplicons of ~550 bp spanning the V3-V4 hypervariable

regions of the 16S small subunit ribosomal RNA gene (herein, 16S rRNA gene). PCR Products were normalised using Sequelprep normalisation plates (Invitrogen, Carlsbad, CA, USA) and the resultant amplicon library was sequenced at a concentration of 5.4 pM with a 0.6 pM addition of Illumina generated PhiX control library. Sequencing was performed on an Illumina MiSeq platform using V3 chemistry (Illumina Inc., San Diego, CA, USA).

Sequenced paired-end reads were joined using VSEARCH (Rognes et al., 2016), quality filtered using FASTX tools (hannonlab.cshl.edu), length filtered with the minimum length of 300 bp, presence of PhiX and adapters were checked and removed with BBTools (jgi.doe.gov/data-and-tools/bbtools/), and chimeras were identified and removed with VSEARCH\_UCHIME\_REF (Rognes et al., 2016) using Greengenes Release 13\_5 (at 97%) (DeSantis et al., 2006). Singletons were removed and the resulting sequences were clustered into operational taxonomic units (OTUs) with VSEARCH\_CLUSTER (Rognes et al., 2016) at 97% sequence identity (Tindall et al., 2010). Representative sequences for each OTU were taxonomically assigned by RDP Classifier with the bootstrap threshold of 0.8 or greater (Wang et al., 2007) using Greengenes Release 13\_5 (full) (DeSantis et al., 2006) as the reference. Unless stated otherwise, default parameters were used for the steps listed. The raw sequence data reported in this study have been deposited in the European Nucleotide Archive under accession number ERS3594341-ERS3594509.

After quality filtering a total of 13725096 sequences were rarefied to an even depth within the phyloseq package (McMurdie and Holmes, 2013). To visualise the relationship between Miseq community profiles from differing sample sites, nonmetric multidimensional scaling (NMDS) was performed using the 'ordinate' function, based on dissimilarities calculated using the Bray–Curtis index. Changes in bacterial diversity related to mean dosage were assessed using Fishers log series [alpha], as this is largely unaffected by sample size and independent if individuals (N) >1000. Diversity was analysed in relation to potential environmental drivers relevant for sites in the CEZ including soil pH, loss on ignition and the calculated dose rates.

## Genetic and epigenetic characterisation using dual restriction enzyme AFLP

A dual restriction enzyme based meAFLP protocol was optimised to assess genetic markers and DNA methylation at these sites. The protocol used is based on parallel use of methylation- and non-methylation-sensitive restriction enzymes (*HpaII* and *MspI*) to treat DNA samples prior to primer ligation and amplification (Xiong et al., 1999). Initially extracted genomic DNA is digested with *EcoRI* and then there is a second digestion step conducted for an aliquot of this sample using either the restriction enzymes *MspI* or *HpaII*. Both *HpaII* and *MspI* recognize a CCGG sequence. *MspI* is able to cut methylated recognition sites (as well as unmethylated ones) thereby providing an assessment of relevant genetic polymorphism. In contrast, *HpaII* is unable to cut at such locations when they are methylated (i.e. only unmethylated recognition sites are cut) which by comparing to *MspI* profiles provides an assessment of epigenetic DNA methylation status.

The meAFLP analysis was conducted in duplicate for all *O. lacteum* and *A. caliginosa* using selective primers for the PCR reactions and analysis on an Applied Biosystems 3130 analyser (Andre et al., 2010). The presence or absence of fragments was scored on chromatograms using GeneMapper Genotyping Software 1.5. Profile bin widths were checked and manually adjusted to encompass all detected peaks. To differentiate signal from background, a Fluorescence Unit (FU) threshold of 40 units was used for a presence/absence binary matrix. All peaks were manually checked for inclusion in analysis. Rare alleles differing only in one individual were initially deleted from the data set. The total number of loci included in the analysis was 202. Fragments were scored as follows: non-methylated state if present in both *EcoRI-HpaII* and *EcoRI-MspI* products (1/1); methylated state if present in either *EcoRI-HpaII* (1/0) or *EcoRI-MspI* (0/1) products (either internal cytosine methylation (0/1) or hemimethylation (1/0)) or absent (0/0). Fragments were classified as “methylation-susceptible loci” if the observed proportion of methylated scores (1/0, 0/1 and 0/0) and “non-methylation fragments”. Principal coordinates (PCO) analysis was also used to visualise the genetic relationship between individuals using GenAlEx ver 6.4.1 (Strat et al., 2017). Site and also potential earthworm strain effects were assessed using the site principal component scores (PCoA1 and PCoA 2) after verification for normality using the Kolmogorov–

318 Smirnov test. Tests were conducted using ANOVA with site and potential strain differences as  
319 factors.

## Results

### *Earthworm distribution, collection and identification by COI barcoding*

Morphotype *O. lacteum* were collected in sufficient numbers ( $\geq 3$  individuals per site) across five sites covering measured surface dose rates from 0.12 - 12  $\mu\text{Gy/h}$ . All sampled locations yielding *O. lacteum* were associated with wetland or marshland habitats (Table 1). Morphotype *A. caliginosa* were collected from three sites covering dose rates from 0.12 - 8  $\mu\text{Gy/h}$ . However, all but one earthworm came from sites with exposure levels  $< 0.2$   $\mu\text{Gy/h}$ . This one *A. caliginosa* collected at site M2: Forest Lake 2 was the only individual to co-occur with *O. lacteum*, indicating an almost completed segregation of the two species across visited sites in the CEZ (Table 1).

To confirm the field based morphological identifications, COI gene sequencing was conducted for all individuals to provide a mitochondrial genotype for comparison with previously published sequences for the two species. For the morphotype *A. caliginosa*, the phylogenetic analysis indicated that all amplified sequences clustered with the *A. caliginosa* COI sequences available in the BOLD database. This correspondence supports the morphotype identification of the individuals as *A. caliginosa*. For *O. lacteum*, a set of successfully amplified product sequences clustered with *O. lacteum* COI sequences available from BOLD within the constructed phylogenetic tree, supporting the morphological identification for these individuals (Supplementary Fig. 2). For a remaining set of *O. lacteum* individuals (38 of 72 individuals), amplification of the COI gene failed, despite best efforts to optimize primers and reaction conditions for PCR. Hence, support for the morphospecies identification for these individuals was not achieved through COI sequencing (see methods). Fortunately, the nuclear genomic loci analysed using the meAFLP method could, however, be used to confirm species identity for these individuals (see below).

### *Soil analysis and dosimetry modeling*

Measured soil  $^{137}\text{Cs}$ ,  $^{90}\text{Sr}$ ,  $^{241}\text{Am}$  and Pu-total, and earthworm gut  $^{137}\text{Cs}$  were close to or below detection limits in all control sites and were highest at the H1 Glubokya Marsh site (Table 2). For modeling the transfer of radionuclides to earthworm tissues at CEZ sites, the external irradiation

from  $^{137}\text{Cs}$  dominates the exposure profile independent of site (Fig. 1), with internal  $^{241}\text{Am}$  representing the next largest dose rate contributor (assuming a radiation weighting factor of 10). The contribution of radionuclides to dose rates were similar across sites (e.g. Fig. 1a/b). Total median modeled dose rates projected for earthworms across the gradient of sites ranged from 0.09 to 45  $\mu\text{Gy/h}$ , these values being correlated the with ambient dose rates, albeit at a factor of 2-3 times higher. The quoted internal dose rates represent only the contribution from actual transfer across the gut or skin to the tissues, although the soil in the gut will act as an additional source of exposure. For  $^{137}\text{Cs}$ , this consideration makes little difference to the total dose rate experienced. There could be a localised dose from  $^{90}\text{Sr}$  to the gut surface, but within one order of magnitude of the estimated internal dose rate, although localised dose may be similar. The dominance of external exposure due to  $^{137}\text{Cs}$  and the relative contributions of the different radionuclides to internal dose are in agreement with dose estimates based upon radionuclide activity concentrations measured in earthworms (Lumbricidae) and soil sampled from the Red Forest (CEZ) in 2014 (Beresford et al., 2019a).

Earthworm size has a relatively small influence on modeled dose rates, with slightly lower  $^{90}\text{Sr}$  dose rates in small earthworms, which is expected from differences in absorption and attenuation. At the most highly contaminated sites (H1 Glubokya Marsh), measured activity concentrations in the gut soil of individual earthworms (29 - 53 Bq/g) showed good agreement with the levels measured in the top 10 cm of soil (49 - 86 Bq/kg). These observations support the modeling predictions that individuals at this site are more highly exposed than earthworms from the other sampled locations.

Site soil pH range from mildly acidic (4.67) at the H1 Glubokya Marsh site with the highest earthworm dose rate to close to neutral (6.23 and 6.66) at two of the low dose rate sites (C1 Glinka, C3 Chernobyl Garden). Soils contained between 4.5 and 15.6% organic matter as measured by loss on ignition, the site with the highest dose rate having the highest value which was almost double that any other site (Table 2). The calculated dose rate was significantly

negatively correlated with soil pH (Pearson correlation -0.86,  $p < 0.02$ ) and positively correlated with soil loss on ignition (Pearson correlation 0.781,  $p < 0.05$ ), with soil pH and loss on ignition also significantly negatively correlated (Pearson correlation -0.78,  $p < 0.05$ ). When the highest dose rate site was removed from the data-set, there was no longer a significant correlation with either soil pH or loss on ignition ( $p > 0.05$ ) indicating the importance of the low pH and high loss on ignition values for the H1 Glubokya Marsh site in driving the significant relationships seen between the soil properties.

#### *Genetic and epigenetic characterisation of earthworms*

Genetic structure within the collected earthworms was assessed using the AFLP analysis for samples at the *Mspl* cleavage site for all sampled individuals. Two distinct groupings were identified based on the obtained profiles. One group (orange squares in Supplementary Fig. 1) comprised confirmed morphotype *A. caliginosa*. These individuals included earthworms collected predominantly from two low exposure sites - C2: Zamozhnyia and C3: Chernobyl gardens and a single individual from medium exposure site M2: Forest Lake 2. Given the similarly low levels of exposure experienced by all but one of the *A. caliginosa*, we focussed our further analysis on *O. lacteum* for which individuals were available from a number of locations with different measured and modeled exposure dose rates. Nonetheless, the *A. caliginosa* data was still valuable for taxonomic assignment.

The remaining AFLP profiles (red circles and green triangles in Supplementary Fig. 1) comprise a single and distinct group within the PCoA plot separated from the *A. caliginosa* samples along PCoA1. This second set of profiles contains all individuals from morphotype *O. lacteum* for which COI sequencing gave both a best BLAST hit against an existing *O. lacteum* COI sequence and for which clustered with a known *O. lacteum* COI reference sequences (green triangle, Supplementary Fig. 1) and also those morphotype *O. lacteum* from which the COI loci could not be amplified and sequenced (red circles, Supplementary Fig. 1). Based on morphological similarity of the individuals to the COI loci confirmed *O. lacteum* and the clustering of the AFLP profiles with

those of the COI confirmed individuals in the PCoA plot, we conclude that all the amplified individuals correspond to one or more clades of *O. lacteum* for which the used primer set does not amplify the COI gene. As likely *O. lacteum*, we concluded that these individuals can be analysed alongside the COI confirmed *O. lacteum* for the assessment of the genetic, epigenetic and microbiome response to ionising radiation at CEZ sites. However, when assessing driver of differences between profiles we used the two potential mitochondrial lineages as fixed factors within ANOVAs of the PCoA scores.

The AFLP analysis based on *MspI* cleavage site markers for all *O. lacteum* showed overlap of profiles between replicate earthworms (Fig. 2). Analysis of PCoA 1 scores indicated a significant site effect (GLM  $F=7.95$ ,  $p<0.001$ ), but not of *O. lacteum* mitochondrial strain (GLM,  $F=0.02$ ,  $P>0.01$ ). Between site differences were found for earthworms from the 6.8  $\mu\text{Gy/h}$  site and all other locations, with the exception of the 0.12  $\mu\text{Gy/h}$  site. The differences in AFLP profiles of earthworms from intermediate dose rate sites compared to those from the higher and lower dose rate sites suggests that exposure to ionising radiation is not the main driver of AFLP profile differences.

To assess DNA methylation patterns in sampled *O. lacteum*, a second AFLP analysis was conducted using the methylation sensitive *HpaII* restriction enzyme. The meAFLP indicated an average of 20.1% of methylation sensitive loci. DNA methylation levels showed no trend of hyper- or hypo-methylation across sites (lowest average 16.7% at an exposure level of 0.12  $\mu\text{Gy/h}$ , highest average 23.4% at an exposure level of 9.1  $\mu\text{Gy/h}$ , Fig. 3a). Principle coordinate analysis of obtained methylation patterns indicated no site-specific structure among the profiles. Sampled individuals showed no segregation within the PCoA on either of the first two principal coordinate axes, which together account for only 20.6% of variance (Fig. 3b). No significant differences in PCoA 1 or PCoA 2 scores were evident (PCoA 1 ANOVA  $F=2.09$ ,  $p>0.05$ ; PCoA 2 ANOVA  $F=1.08$ ,  $p>0.05$ ). Consistent methylation levels and the overlap of methylation patterns among earthworms sampled from sites with different radiation dose rates, suggests no effects of radiation exposure on global DNA methylation patterns at CEZ sites for *O. lacteum*.

Sequencing of the 16S rRNA loci amplified from *O. lacteum* gut DNA identified 18870 OTUs at the 97% similarity threshold. An NMDS analysis using data for sequences allocated to these OTUs for each earthworm microbiome indicated a clear segregation of all individuals from each site within an NMDS analysis plot (Fig. 4). NMDS1 and NMDS2 scores were significantly correlated with median dose rate, soil pH and soil loss on ignition in all cases ( $p < 0.001$  all cases). However, due to the small number of sites, such correlations with average dose rate may be a potential artifact due to co-correlation effects. For this reason, to determine whether a given environmental variable may be a driver of microbiome change, we assessed the structure of this relationship – notably the monotonic nature of the response (i.e. score increase or decrease progressively in relation to environmental variable level). This site based separation by OTU profiles, did not show a monotonic relationship with radiation exposure level along the NMDS 1 axis, with low exposure level and high exposure levels sites having high NMDS 1 scores and medium exposure sites low values (Supplementary Fig. 3A). There was also a non-monotonic relationship of NMDS 1 score with site soil pH, the highest axis values found for the sites with the most acidic and alkaline soils (Supplementary Fig. 3B). There was an approximate monotonic relationship of NMDS 1 score with site soil loss on ignition (Supplementary Fig. 3C), indicating that soil organic matter composition may act as a critical driver of soil bacterial community structure either directly or through indirect effects on other soil properties such as water holding capacity which may affect soil responses to drought or frost. NMDS 2 score was close to monotonic related to calculated dose rate (Supplementary Fig. 3D). However, as there is co-correlation of the environmental drivers, both soil pH and loss on ignition also show a monotonic relationship with NMDS 2 score (Supplementary Fig. 3E and 3F).

Diversity expressed as Fishers log alpha was highest in the bacterial gut microbiome samples in *O. lacteum* earthworms from the two lowest exposure sites (C1 Glinka, C4 Marsh) and lowest in the two highest exposure sites (H1 Glubokya Marsh, M2 Forest Lake). Diversity increased systematically with increasing median earthworm dose rate (Fig. 5A). As pH is strongly co-

460 correlated with earthworm dose rate, there is also a relationship of increasing diversity at high soil  
461 pH values. Diversity was not systematically related to soil loss on ignition, with high diversity at  
462 both intermediate and high soil loss on ignition sites (Fig. 5B).

463

## Discussion

The scale and devastating nature of the Chernobyl accident has created a legacy of exposure for wildlife living around the site of the former power plant. Radioecologists have studied the long-term effects of the resulting exposure, both to support local management and to better understand any long-term effects on individuals, populations, and ecosystems. Comprehensive reviews of the phenotypic effects observed in wildlife experiencing prolonged exposure to elevated radionuclide levels in the CEZ have highlighted the range of studies on the structure and function of exposure populations and communities from soil microbial communities to charismatic vertebrate wildlife (e.g. Beresford et al., 2016; Geras'kin et al., 2008; Hinton et al., 2007; Lourenco et al., 2016; Steinhauser et al., 2014). Within the range of published studies, there is a lack of consensus on the long-term effects of chronic radiation exposure for wildlife in the CEZ (Beresford et al., 2019b). The impacts of radiation exposure on the hologenome and subsequent impacts on exposure and subsequent generations have been identified as one factor that may contribute to the impacts of long-term exposure in the CEZ (Horemans et al., 2019). Understanding such effects may benefit from addressing uncertainties relating to the chronic effects of radiation exposure.

The prolonged exposure of soil invertebrates to long-lived contaminants has been shown to change population genetic and epigenetic traits that underpin the development of tolerance (Horemans et al., 2019). The relatively high reproductive rate of many invertebrates enables rare or novel gene variants associated with adaptive traits to spread relatively quickly throughout populations under selection pressure. Many invertebrates have been shown to develop adaptation to contaminants (Klerks & Weis 1987; Posthuma & Van Straalen 1993). For earthworms, tolerance to metal exposure has been shown in populations inhabiting sites polluted with a number of different metals. Andre et al. (2010) used genetic marker analysis to identify an 'ecological island' with little genetic overlap in *L. rubellus* populations inhabiting lead polluted and clean soils under different pH conditions. Mutations in the Ca-transport gene SERCA were found between populations, identifying this locus as a possible mechanism for adaptation. Langdon et al. (1999) also working with *L. rubellus* found that individuals inhabiting two mining areas heavily polluted

with arsenic and copper (Devon Great Consols, Carrock Fell) could survive in arsenic-spiked soil that was acutely toxic to earthworms from an uncontaminated location. This tolerance was preserved following culturing over two generations, suggesting a genetic basis for the adapted phenotype (Langdon et al., 2009). Kille et al. (2013) used mitochondrial (COI) marker analysis and meAFLP to assess the genetic and epigenetic traits of *L. rubellus* from the same Devon Great Consols mine site studied by Langdon et al. (2009). Both the COI analysis and AFLP markers identified two genetic lineages of *L. rubellus* at the mine site consistent with previous findings (Anderson et al., 2017; Giska et al., 2015; Spurgeon et al., 2016). For the most genetically diverse lineage (A), segregation of local collection site populations by AFLP profiles was seen. For the second, less diverse, lineage (B), this genetic segregation by AFLP profile was not seen, however, site segregation by meAFLP profiles was observed. This indicates a contribution of the epigenome to the observed adaptive phenotype in Lineage B *L. rubellus*. This unique finding indicates the need to assess how both genetic sequence changes and DNA methylation can play a role in the development of adaptive phenotypes in earthworms.

An initial survey of Chernobyl earthworm communities identified that species are patchily distributed across the exclusion zone. The dominant soil type in the region is sandy in nature with characteristically low pH and organic matter content. Such free draining acid soils have been found to be poorly suited for earthworms, which maintain larger and more diverse communities in areas with high clay or silt content, high water holding capacity and high electrical conductivity (Nuutinen et al., 1998; Valckx et al., 2009). The main locations from which earthworms were collected were associated either with water bodies (lake or river margins, marshland) or improved soils managed as domestic gardens in areas of past human habitation. This indicates that soil hydrological status acts as a major driver of earthworm distributions within the CEZ.

Two species of earthworms were found in sufficient numbers to provide potential samples for analysis. Both *O. lacteum* and *A. caliginosa* are endogeic species that live in the mineral soil layers. Exposure in this habitat would be lower than to epigeic species living in the top-soil, since

almost 20 years after the accident, radionuclides remain largely in the upper 0-20 cm soil layers (Almgren and Isaksson, 2006; Ivanov and Kashparov, 2003). However, at the soil sampling depth used (10 cm), calculated dose rates would be generally representative for species living within the mineral soil layer. The individual measurements of relevant external and internal radionuclide concentrations for dosimetry assessment confirmed this exposure. Among the earthworms species found during the preliminary survey and main field sampling campaign, only *O. lacteum* was found in sufficient number across CEZ sites with comparatively low, medium and high exposure. *O. lacteum* is an endogeic earthworms species that is able to undertake both sexual and parthenogenetic reproduction, which may be relevant both for its relative prevalence in the CEZ and also potentially for its adaptation to local environmental conditions. *A. caliginosa*, another albeit larger endogeic earthworm species, was in contrast collected only from sites with near background levels. Too few sites were sampled to attribute the absence of *A. caliginosa* to the prevailing exposure levels. Absence is likely to be explained simply by the lack of suitable habitat for this species at the more contaminated sites.

Our analysis of the *O. lacteum* hologenome included measurement of genetic, epigenetic and microbiome characteristics. However, while covering key aspects, not all hologenome traits were included. For example in assessing epigenome responses, we focussed on an established method to measure coarse DNA methylation coverage. These DNA methylation marks were not mapped to genomic locations to provide insights in their functional role in gene regulation. Further, other potential epigenetic changes linked to the modification of histone protein and expression of regulatory microRNAs were not measured. These epigenome components have previously been found to be active in earthworms (Gong et al., 2010; Novo et al., 2015). Hence, their future inclusion within a more complete assessment of hologenome responses to ionising radiation exposures may be warranted.

The genetic analysis of *O. lacteum* using AFLP markers at *MspI* restriction sites indicated that all morphotype earthworm from this species exist as a single group. Using the COI primers,

sequences from 53% of all collected morphotype *O. lacteum* failed to amplify despite best efforts. The reasons for this failure are currently not clear, but may be related to the presence of specific point sequence variations in the primer binding region of the COI sequence in these individuals. The presence of these polymorphisms may be indicative of the cryptic mitochondrial lineages in this species, as has been found for *O. lacteum* (Klarica et al., 2012) and also commonly for other earthworm including *L. rubellus* (Anderson et al., 2017; Andre et al., 2010), *Eisenia fetida* (PerezLosada et al., 2009) and *Allolobophora chlorotica* (King et al., 2008). The more comprehensive AFLP data, however, refutes the presence of cryptic *O. lacteum* species, as the PCoA analysis of the AFLP data shows that CEZ *O. lacteum* comprise a single clade.

Site-specific structure was observed within the *MspI* restriction site AFLP analysis. This was not, however, correlated with modeled earthworm dose rate. This suggests that there has been no selection relating to the ionising radiation exposure. Similarly, we found no difference in DNA methylation levels or structure within the meAFLP analysis, indicating that there is no site, and hence ionising radiation exposure level, influence on the distribution of DNA methylation within the *O. lacteum* genome. Many contaminants have been shown to alter gene methylation patterns in invertebrates (Santoyo et al., 2011) and plants (Chinnusamy and Zhu, 2009). In response to ionising radiation exposure in the CEZ, hypermethylation of DNA has been observed in pine trees (*Pinus sp.*) and *Arabidopsis thaliana* (Kovalchuk et al., 2004; Kovalchuk et al., 2003) and it has been suggested that individuals of adult pale blue grass butterfly *Zizeeria maha* at Fukushima have shown inherited abnormalities from the F1 to the F2 generation (Hiyama et al., 2012). Epigenetic mechanisms were proposed to play a role in both cases. Absence of a clear indication of changes in patterns of DNA methylation measured using meAFLP for *O. lacteum* may indicate that adaptive phenotypes may be regulated through other epigenome components. Alternatively, it is possible that exposure at the sampled CEZ sites is not sufficient to cause significant epigenetic changes in this species. However, in this context, it is important also to consider that meAFPL provides only a very course assessment of one aspect of the response to the epigenome to perturbations. Other methods for quantifying DNA methylation targeting either speciifc genes through methylation-

specific PCR or genome wide methylation analysis using high throughput sequencing approaches may better resolve any specific DNA methylation changes resulting from radiation exposure. Further, there are other epigenetic mechanisms that may also play a role.

The analysis of the structure of the CEZ *O. lacteum* microbiome indicated clear site structure in the composition of gut bacteria as analysed using 16S RNA gene loci amplification and sequencing. The earthworm microbiome has previously been found to be shifted in response to the presence of arsenic in contaminated soils at a mine site (Pass et al., 2015). In this study, the earthworm-associated microbiome was found to differ from the surrounding environment. Several taxa observed in uncontaminated control microbiomes were found to be suppressed by metal/metalloid field exposure, including the eradication of the hereto ubiquitously associated *Verminephrobacter* symbiont, which raises implications to its functional role in the earthworm microbiome (Pass et al., 2015).

It has been shown that the earthworm gut bacterial microbiome is a combination of soil associated species passing through the gut and also a range of strongly host related core species present across different soils (Liu et al., 2018; Pass et al., 2015). As the earthworms sampled in this survey were not starved or washed to remove soil in the gut, both core *O. lacteum* and also soil associated species would be present. Microbiome structure and diversity was systematically related to site soil properties. Analyses through 16s rRNA sequencing have indicated that soil properties can significantly affect the bacterial community (George et al., 2019; Plassart et al., 2019). Griffiths et al. (2011) showed that pH was a dominant driver of national patterns of soil bacterial species distribution, with other environmental variables and climatic variables and spatial correlations at local scale also influencing community structure. Given that the soil bacterial community contributes a significant proportion of earthworm microbiome species, the potential exists for soil properties to be responsible for differences in the microbiome.

*O. lacteum* gut bacterial microbiome structure was site specific and was weakly correlated with dose rate. However, across sites there was also co-correlation between earthworm dose rates and other soil properties, notably pH. Subtle shifts in soil bacterial community structure have previously been shown to respond to radiation exposure, although at much higher dose rates than those quantified here (Jones et al., 2004; McNamara et al., 2007; Niedree et al., 2013). Hence, changes in earthworm gut microbiome structure and diversity may be related to soil dose rates. However, the widely known role of soil pH as a driver of bacterial community structural difference makes the attribution of the observed difference in microbiome structure to radiation exposure challenging. Further, soil pH has been shown to be a key determinant of the speciation of metals and radionuclides in soil (Lofts and Tipping, 2011; Vandenhove et al., 2007), with resulting effects on bioavailability (Hegazy et al., 2013; Spurgeon et al., 2006). Hence, as well as the potential direct effects of radionuclide and pH, there may be interactive pH effects on radionuclide bioavailability which may complicate the attribution of *O. lacteum* gut bacterial community variation to any single driver.

## **Conclusions**

Prevailing habitat, soil and climatic conditions mean that the distribution of earthworms in the CEZ is spatially limited. Our survey suggests that earthworms are restricted to sites associated with water bodies and in abandoned urban gardens. Our hologenome analyses indicate that there is no major impact of the prolonged exposure of earthworms to radionuclides on the measured genetic or epigenetic characteristics of earthworms collected across our studied sites. Earthworm gut bacterial microbiome community did show strong site specific structure that could be related to the prevailing dose rate predicted for earthworms living at each site. Co-correlation of other soil properties with dose rate and potential interactions, however, means that it is not possible to attribution of these changes specifically to radionuclide exposure. A wider survey is needed to more robustly address questions relating to the impacts of radionuclide exposure on the microbiome. Due to their limited distribution in the CEZ earthworm may not be the best study group for such an extended survey. Robust wide-scale microbiome community structure is a potentially

631 effective approach, although it is acknowledged that microbe may be among some of the most  
632 radio insensitive groups of organisms, the interplay between host health and microbiome structure  
633 may indicate a wider interaction at the level of the hologenome.

### ***Legends to figures***

Figure 1. Relative proportionate contribution of different measured radionuclides at sites with median ambient dose rates of 0.24 (Left pie chart) and 45  $\mu\text{Gy/h}$  (Right pie chart B) for earthworms sampled in the CEZ.

Figure 2. Principle coordinate analysis of *O. lacteum* *MspI* AFLP multi-locus profiling collected at five sites in the CEZ with different soil total earthworm dose rates.

Figure 3. (Panel A) Percentage of methylated susceptible loci for *O. lacteum* collected at five sites in the CEZ with different soil total earthworm dose rates ( $\mu\text{Gy/h}$ ); and, (Panel B) principle coordinate analysis for *MspI/HpaII* meAFLP analysis for methylation loci for *O. lacteum* *MspI* AFLP multi-locus profiling collected at five sites in the CEZ with different total soil earthworm dose rates.

Figure 4. Non-metric multidimensional scaling plot of 16S rRNA gene sequence analysis of gut microbiomes of *O. lacteum* collected at five sites in the CEZ with different total soil earthworm dose rates and the relationships with environmental vectors oriented in the direction of greatest increase with length is proportional to their correlation with the two NMDS axes.

Figure 5. Diversity of bacterial sequenced OTUs within the earthworm microbiome for *O. lacteum* collected from five locations within the CEZ expressed as Fischer's alpha in relation to soil (A) pH and (B) loss on ignition, bars are shaded according to earthworm dose rate ( $\mu\text{Gy/h}$ ).

Fig. 1

Fig. 2

Fig. 3

Fig. 4

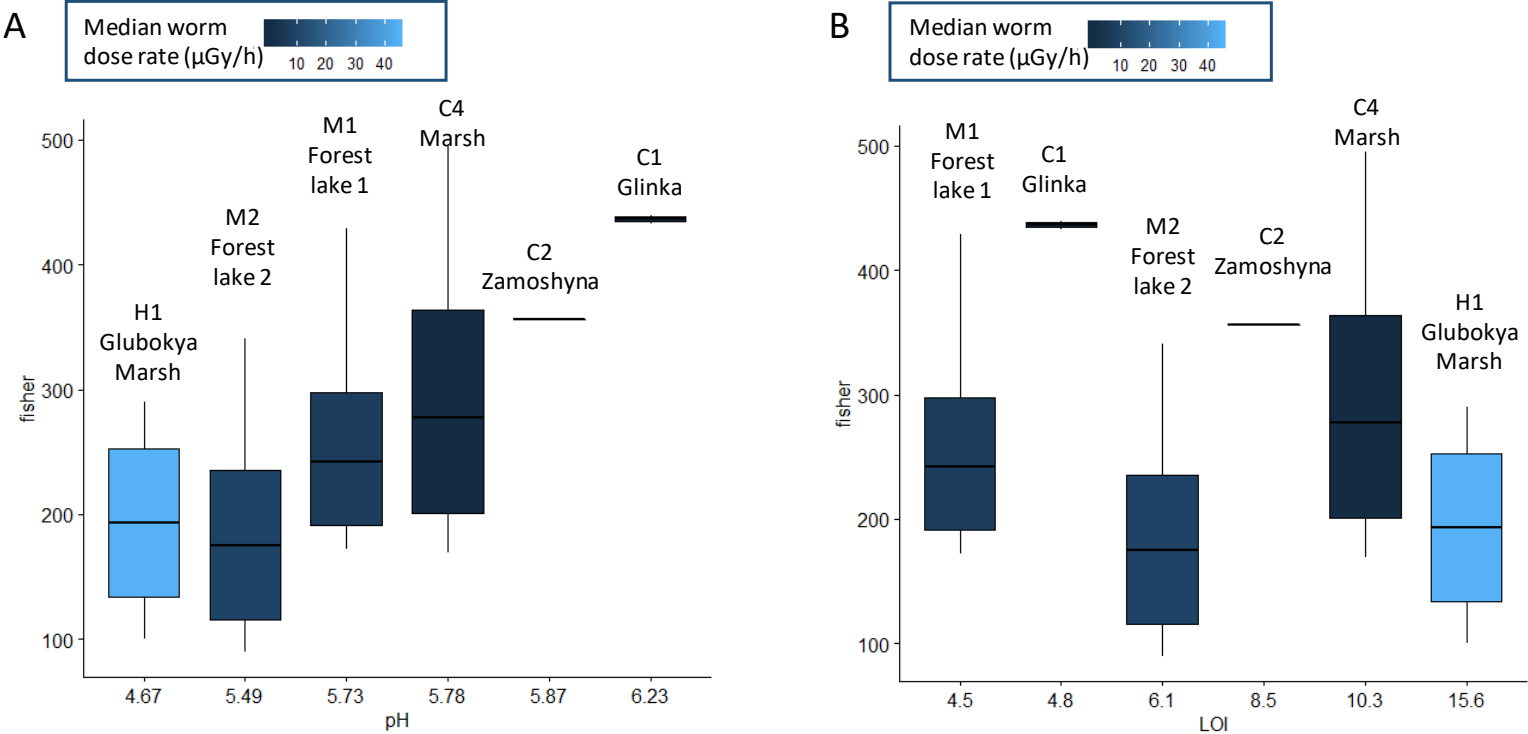

Fig. 5

Supplementary Figure 1. Principle coordinate analysis of AFLP *Msp*I multi-locus profiles for morphotype *O. lacteum* and *A. caliginosa*: morphotype *A. caliginosa* confirmed by COI sequencing cluster to the right; morphotype *O. lacteum* both confirmed by COI sequencing and which also fail to amplify for the COI locus cluster to the left as a single group.

Supplementary Figure 2. Phylogenetic gene tree showing the relationships between individual collected earthworms successfully amplified and sequenced for the Cytochrome oxidase I loci; branch distance indicates the degree of base substitutions between individual; all samples labeled starting P1 or P2 correspond to study samples with all other samples corresponding to reference specimen sequences.

Supplementary Figure 3. Relationship between NMDS axis 1 score and soil (A) median earthworm dose rate ( $\mu\text{Gy/h}$ ), (B) pH, (C) loss on ignition and NMDS axis 2 score and soil (D) median earthworm dose rate, (E) pH, (F) loss on ignition.
